As Hidrology is science of learning natural water move and distribution laws, their relationships with surrounding environment, qualitative and quantitative changes. Comprehensive study of hidrology has great importance for a proper evaluation of water sources and resouces. Still 5-6 thousand years ago waterworks, irrigation canals, reservoirs, dams and so on. was built and studied in ancient Egypt, Mesopotamia, China, South and Central America, Nowadays, in many countries (Russia, USA, Germany, France, Spain, etc.) hydrological information is printing in annual bulletins and the observational data of the world’s rivers is published by UNESCO in special books. These books obtain information about monthly and annual average water flow of the 250 rivers. Maps of various river flow have been drawn in many countries, including Russia, China, USA, Canada, Australia and others. It should be noted that these maps can be considered to be sufficiently accurate and reliable because they are designed according to a large number of observation stations.

Up to early XIX century information about the water sources of Azerbaijan have been found in the traveller’s works. The first measurement with the devices was started since 1814 and the main purpose was to explore whether the part of Kura river from its mouth to the Mingachevir city is suitable for navigation. Since 1911 each year the results of the hydrological survey of the Caucasus water department has been published in the “Report”ing and “Bulletin”. During this 42 reports comprising tables, graphs and maps was published. Among published since 1913 by Caucasus “Works” A.M. Esse’s “Hidrometik statistical methods of data processing”, “The study of the flood” and especially “Hidrography of the South Caucasus” are more interesting and important books. In the last book was listed short hydrographic characteristics and maps of 29 rivers of Azerbaijan.
Cartographic analysis hydrometeorological atlas of the Caspian Sea

Last years in Azerbaijan is one of the most significant events area hidrological mapping in 2014 year it is the edition “Hydrometeorology atlas of the Hazar”. This atlas consist 300 pages and redactor was academic NASA, director of geography institute Ramiz Mammadov’s. We can be divided this atlas into seven sections.

The first section name is “Mugaddima” and about the hydrometeorology of Hazar sea. In this section contained observation points, their durations, the observations of the polling stations, measurements on the periodicity information coastal zone and open area of the sea. In this atlas according principle of deparation squares depths of the sea waters. This section is compiled about the Caspian countries.

The second section name is “Geography division”. This section consist on bathymetry, bottom relief of the sea and geomorphology maps, also explain how to create map.

“Hydrology” which is considered one of the main part and the third section of atlas given monthly, yearly temperature distribution of surface layer in are of Hazar. Azerbaijani sector of the Caspian Sea in different parts of the distribution of temperature in different seasons of the year on the custom maps were drawn. Surface waves of the sea, taking into account the special importance of economic activity in human life, that is why this hydrological element taking is a great place of this atlas. Monthly distribution of its marine waters, diverse and fast winds, height, length, period, and phase velocities are displayed maps. In this section, as well as salinity, transparency, flow and hydrological elements, such as the formation of ice time and space distributions are reflected in the maps. The temperature of the sea, absolute and relative humidity, clouds, radiation and albedo, wind mode, speeds and directions “meteorology of the Caspian Sea”, which is reflected in the fourth section.

The fifth section is devoted to the interaction of the sea atmosphere. Evaporation from the sea surface temperature, heat exchange between the atmosphere, the sea, heat capacity, heat balance etc. is the basis of this section. The sixth section is devoted to changes in the level of the sea. Finally, the atlas is completed with the issuance of the information base used in the data. This atlas is developed to be used in various economic activities in the Caspian Sea Atlas.

Modern technology drawing map

Geographic information systems currently based on the use of modern technology in the world, with maps are drawn. As a first step in this direction on the basis are underway for the establishment of a single electronic Cartographic base. There established single cartographic base for 1:2000, 1:5000, 1:10000, 1:25000, 1:50000, 1:100000, 1:200000, 1:500000, 1:1000000 scales national, territorial and municipal purposes. Creation to this maps using the topographic maps and plans, or if no geo-
The hydrological mapping and methods in Azerbaijan

coding raster layers of earth materials from remote sensing. If the case according to the substance classification of the hydrological maps are included in the group thematic maps. In turn, the classification of hydrological maps can be divided into small groups the system of rivers, precipitation, channels, and ditches, lakes, springs, reservoirs, artificial water basins, ocean, sea, and fresh water reserves and others. It has a great need for the country economically in the creation of maps in electronic format. So on the map precipitation in the basins by placing artificial and natural water bodies, the amount of data possible evaporation of water can calculate the probability of flooding. For this purpose should be done zoning the area and it is one of the most important generalization method. It is known that the land zoning system it is to identify and study the relations between the organization and hierarchy process. Each regional data are taken in division of territory or a separate thematic maps that can be made, based on these maps, daily, weekly, annual. Map compilation of previous periods a process that requires a lot of effort and time, but with the development of technology in the modern world map compilation had the opportunity to remove these restrictions. The innovations in the methods of drawing up maps of the country is currently experiencing a period of development. The new software to improve the quality necessary for the preparation of the information of the map, save large amounts of information is able to conduct a survey at any time.

![Picture 1. The previous hydrological map of SSDR](image)

At present in Azerbaijan there is no electronic library or national bank of hydrological data open for everyone, and the existing electronic bases of hydrometeorological data of the departments of hydrology and meteorology of the State Committee on Ecology and Environmental Control of Azerbaijan are open only for official use and they are paid figure 3 USD. For this reason the students, masters, postgraduate students, persons working for doctor’s up to now use the traditional methods for collection and analysis of hydrometeorological
information. Taking into account the importance of the national geoinformation creation system of the Azerbaijan geographical information, of Azerbaijan, in particular the hydrometeorological one we have created geoinformation maps of water resources of Azerbaijan, where are reflected the basic hydrological characteristics in the forms maps, diagrams and marks which the students, masters, postgraduate students and other users can use freely all hydrometeorological data. For creation of geoinformation map of indices of water resources of Azerbaijan we at first compiled a digital map of river basins and then electronic table of digital hydrological data.

The review hydrological research foreign countries

As uniform spatial models of the Earth’s surface, maps provide area-wide representation of landscape features relevant to the time and purpose of surveying (Rumsey and Williams, 2002). Maps involve a defined scale and legend (otherwise it is not a map). Relying on the map scale, spatially accurate and quantitative analysis is possible. Based on the map legend, interpretation is straightforward and unambiguous as long as the map is preserved in good condition.

During the early days of cartographic science, with the rapid evolution of geodesy, new maps were thought to be inherently better and more accurate than older maps, and historic maps were therefore not studied in detail. In the initial stage of historic map investigations, differences compared to the current situation were assessed by cartometric techniques and regarded as errors (Stegena, 1982; Cholnoky, 1918).

The Hydro Reference Overlay is an out of the box base layer that engineers and watershed managers can use in site maps on their desktop, or in web maps on ArcGIS Online, or their own custom web mapping applications. The Hydro Reference Overlay - Medium Scales map template provides the tools that you will need to create the 144K, 72K, and 36K scale levels of the Hydro Reference Overlay map. You just simply follow the instructions in the template package, and essentially pour your data into the template to create your own hydro-centric reference map. Hydrological map, chart showing such hydrologic features as rivers and streams; the purpose and content of these maps vary according to the country of their origin. Some maps are used as supplements to a detailed written text, whereas others, such as the USGS Hydrologic Investigations Atlases series, provide only a brief and general discussion as the text. Since hydrology embraces the many subsystems relating to water, the maps may be constructed for each individually or may combine the features of more than one subsystem.

Rain gauge data is used to measure total precipitation over a drainage basin, and there are different ways to interpret that data. If the gauges are many and evenly distributed over an area of uniform precipitation, using the arithmetic mean method will give good results. In the Thiessenpolygon method, the drainage basin is divided into polygons with the rain gauge in the middle of each polygon assumed to be represen-
The hydrological mapping and methods in Azerbaijan

tative for the rainfall on the area of land included in its polygon. These polygons are made by drawing lines between gauges, then making perpendicular bisectors of those lines form the polygons. The isohyetal method involves contours of equal precipitation are drawn over the gauges on a map. Calculating the area between these curves and adding up the volume of water is time consuming. Isochrone maps can be used to show the time taken for runoff water within a drainage basin to reach a lake, reservoir or outlet, assuming constant and uniform effective rainfall. The USGS has a distributed water database that is locally managed. Surface water, groundwater, and water quality data are compiled from these local, distributed databases into a national information system. The groundwater database contains records from about 850,000 wells that have been compiled during the course of groundwater hydrology studies over the past 100 years. Information from these wells is served via the Internet through NWISWeb, the National Water Information System Web Interface. NWISWeb provides all USGS groundwater data that are approved for public release. This large number of sites is excellent for some uses, but complicates retrievals when the user is interested in specific networks, or wells in an active water-level measurement program. These “groundwater watch” web pages group related wells and data from these active well networks, and provide basic statistics about the water-level data collected by USGS water science centers for Cooperative Programs, for Federal Programs, and from data supplied to us by our customers through cooperative agreements. The National Hydrography Dataset (NHD) and Watershed Boundary Dataset (WBD) are used to portray surface water on The National Map. The NHD represents the drainage network with features such as rivers, streams, canals, lakes, ponds, coastline, dams, and streamgages. The WBD represents drainage basins as enclosed areas in eight different size categories. Both datasets represent the real world at a nominal scale of 1:24,000-scale, which means that one inch of The National Map data equals 2,000 feet on the ground. To maintain mapping clarity not all water features are represented and those that are use a moderate level of detail. The NHD and WBD are digital vector datasets used by geographic information systems (GIS). These data are designed to be used in general mapping and in the analysis of surface water systems. In order to make a map these data must be used by a GIS to render the data and then print a map or make an image. The NHD is portrayed on the US Topo map product produced by the USGS and the NHD and WBD can be viewed on the Hydrography Viewer or the general mapping oriented The National Map Viewer. In mapping, the NHD and WBD are used with other data themes such as elevation, boundaries, transportation, and structures to produce general reference maps. The NHD and WBD are often used by scientists using GIS. GIS technologies take advantage of a rich set of attributes imbedded in the data to generate specialized information. These analyses are possible because the NHD contains a flow network that allows for tracing water downstream or upstream. The NHD and WBD use an addressing system based on reach codes and linear referencing to link specific information about the water such as water discharge rates, water quality, and fish population. The WBD exists in six levels of a nested hierarchy permitting the analysis
to determine which drainage basin a particular location is enclosed in. This makes it possible to determine which rivers and lakes could be affected by an event such as a toxic spill. Using basic NHD features like flow network, linked information, and other characteristics, along with one of the six levels of WBD areas, it is possible to study cause and effect relationships, such as how a source of poor water quality upstream might affect a fish population downstream.

At present the hydrological measurements, calculations, forecasts and map compiling are carried out by the help of automatized method. In order to realize all these tasks a new science called computer hydrology (comhydrology) is used. The comhydrology develops at the joint of hydrolog, geoinformatics and cybernetics as a compound part of computer geography [1, 2]. The basic task of this science is the automatized measurement, preservation and processing of hydrological information of water objects of the Earth by the help of space ships, artificial satellites and flying apparatuses over the surface of the Earth connected with over ground computer centres of various countries. The cartographical task of comhydrology is solved by the programs of geoinformation system (GIS). The GIS allows hydrologists to analyze the initial information, carry out the measurements and calculations, construct the diagrams and maps directly by computer (keeping contact with stationary artificial satellite system of GPS and QLONAS).
Conclusion

At the result we can say as follows:

1. The innovations in the methods of drawing up maps is currently experiencing a period of development in Azerbaijan Republic. In this case, scientists and experts from foreign countries to get acquainted with modern hydrological map compilation methods and techniques would be important.

2. The important issues of the hydrological mapping that is using Geographical Information system, drawing maps all data of hydrology, create hydrological region, to take information from meteorology stations and other the relevant structures, prior to forecast conditions extremal situation.
